Shape optimization by pursuing
diffeomorphisms

R. Hiptmair and A. Paganini

October 17, 2014

Abstract
We consider PDE constrained shape optimization in the framework of finite element discretization of the underlying boundary value problem. Our approach employs (i) B-spline based representations of the deformation diffeomorphism, and (ii) superconvergent domain integral expressions for the shape gradient. We study the balance of the discretization errors of the finite element method and the B-spline approximation. We provide numerical evidence of the performance of this method on a test case stemming from the class of exterior Bernoulli free boundary problems.

1 Introduction

Physical phenomena are described by mathematical models that link input and output quantities. An important task in engineering is to find optimal values of the input so that a target output is minimized. In shape optimization the target output depends on the shape $\Omega$ of an object. This dependence is modeled via a shape functional $\mathcal{J}$.

In several relevant applications the shape functional $\mathcal{J}$ depends, additionally, on the solution of a boundary value problem (BVP) stated on $\Omega$. In this case we speak of PDE constrained shape optimization. These optimization problems are highly non-linear and can rarely be solved analytically. Usually, one has to content oneself with approximate optimal shapes obtained with iterative optimization algorithms combined with approximate solutions of the underlying BVP. Clearly, the quality of the approximate optimal shapes heavily depends on the choice of the numerical method used to retrieve them.

An accurate method to solve PDE constrained optimization problems has been developed relying on boundary element method solutions of the underlying BVP [11, 12]. However, the bulk of literature considers discretizations
by means of the finite element method (FEM) [2, 6–8, 13, 18–21, 23]. In this case we can distinguish between moving-mesh and fixed-mesh methods.

The former discretize an initial guess $\Omega_0$ with a mesh and then optimize the coordinates of the mesh nodes [2, 21, 23]. This is a very delicate task because the mesh might get distorted or self-intersect as the optimization routine proceeds [3, 4].

Among the fixed-mesh methods, the two most popular approaches are level-set methods and free-form deformation methods. In the level-set approach, the boundary of the optimal domain is represented as the zero-level of a function [5]. The optimization is then carried out by updating this function. Again, this is a delicate process because, to identify the boundary of the optimized domain, the level set function should have steep slope at the zero-level. However, as the optimization proceeds, it is observed that level-functions tend to become flat [22].

On the other hand, free-form deformation methods [7, 19] recast the shape optimization problem as an optimal control problem. Shapes are parametrized by applying a transformation to the initial guess $\Omega_0$. This transformation is constructed with (piecewise) polynomials defined on a lattice of control points, and optimization is carried out on their coordinates. This approach allows to preserve the approximation properties of FEM. However, the infinite dimensional shape optimization problem is replaced with a counterpart with a fixed small number of control parameters, and the dependence of the quality of the discrete solution on the number of control parameters is not clear.

We present an algorithm developed to preserve and exploit the approximation properties of FEM, and that allows for arbitrarily high resolution of shapes. Similarly to the free-form deformation approach, we recast the shape optimization problem as an optimal control problem. Shapes are parametrized by letting a diffeomorphism act on an initial shape $\Omega_0$. Pursuing a Ritz approach, we discretize the diffeomorphism with conforming basis functions based on cubic B-splines. We show that, under reasonable assumptions, the sequence of optimal discrete solutions converges to the global minimum as the dimension of the trial space tends to infinity. We also investigate the impact of FEM approximations in the context of elliptic PDE constrained shape optimization and formulate a descent method that enjoys superconvergence in the approximation of the Fréchet derivative. We test the performance of the proposed method on a model problem stemming from the class of exterior Bernoulli free boundary problems.
2 Shape optimization in parametric form

Let $D \subset \mathbb{R}^d$ be bounded and convex domain (hold-all domain), and let $\Omega_0$ be a compact subset of $D$ with Lipschitz boundary. We fix $\varepsilon > 0$ and define the set of admissible shapes as

$$U_{ad}(\Omega_0) := \{ T_V(\Omega_0); T_V = I + V, \| V \|_{C^1(D; \mathbb{R}^d)} \leq 1 - \varepsilon \}.$$  \hspace{1cm} (1)

Note that the map $T_V := I + V$ is a diffeomorphism whenever $\| V \|_{C^1(D; \mathbb{R}^d)} < 1$ [2, Lemma 6.13]. Let $J$ be a real functional defined on $U_{ad}(\Omega_0)$, and let $\tilde{J}$ be defined by

$$\tilde{J} : B_{1-\varepsilon}^1 \to \mathbb{R}; \ V \mapsto J(T_V(\Omega_0)).$$

where $B_{1-\varepsilon}^1$ denotes the $C^1(D; \mathbb{R}^d)$ closed ball of radius $1 - \varepsilon$ centered in 0.

The shape optimization problem

$$\inf_{\Omega \in U_{ad}(\Omega_0)} J(\Omega)$$

can be recast as

$$\inf_{V \in B_{1-\varepsilon}} \tilde{J}(V).$$  \hspace{1cm} (2)

**Theorem 1.** Let $\tilde{J}$ be continuous with respect to the $C^1(\overline{D}; \mathbb{R}^d)$-norm and restrict the shape optimization problem (2) to

$$\inf_{V \in B_{1-\varepsilon}^1} \tilde{J}(V).$$  \hspace{1cm} (3)

Then, there exist a vector field $V^* \in C^1(\overline{D}; \mathbb{R}^d)$ so that

$$\tilde{J}(V^*) = \inf_{V \in B_{1-\varepsilon}^1} \tilde{J}(V).$$

**Proof.** We follow closely [2, Thm 5.12]. The main ingredient is the compact embedding $C^2(\overline{D}; \mathbb{R}^d) \overset{\varepsilon}{\hookrightarrow} C^1(\overline{D}; \mathbb{R}^d)$, which holds for $D$ convex or, more generally, if “every pair of points $x, y \in D$ can be joined with a rectifiable arc in $D$ having length not exceeding some fixed multiple of $|x - y|$” [1, Thm 1.34].

A minimizing sequence of (3) is bounded (by definition of the optimization problem). Thus, by compactness, we can extract a subsequence that converges to a limit function $\hat{V}$ in the $C^1(\overline{D}; \mathbb{R}^d)$-norm. Finally, the continuity assumption on $\tilde{J}$ implies $\hat{V} = V^*$. \hfill $\Box$

**Remark 1.** The continuity assumption on $\tilde{J}$ in Theorem 1 is fulfilled by most of the shape functionals considered in the literature. For instance, this is the case for the volume and the surface area shape functionals.
Remark 2. A counterpart of Theorem 1 still holds if the function spaces $C^1(D;\mathbb{R}^d), C^2(D;\mathbb{R}^d)$ are replaced by $W^{1,\infty}(\mathbb{R}^d;\mathbb{R}^d), W^{2,\infty}(\mathbb{R}^d;\mathbb{R}^d)$, respectively. However, having approximations by means of the Ritz method in mind, we restrict our framework to separable spaces.

Remark 3. There is little hope for uniqueness in this framework. Let $V^*$ be an optimal solution. If there is a vector field $\tilde{V} \neq I$ so that $\tilde{V}(\partial \Omega_0) = \partial \Omega_0$ (from the set point of view), then the composition $V^* \circ (I + \tilde{V})$ is an optimal solution, too.

Approximate solutions can be obtained easily with a Ritz approach.

Theorem 2. Let $\{V_N\}_{N\in\mathbb{N}}$ be a nested sequence of $C^2(D;\mathbb{R}^d)$-conforming trial spaces that satisfies

$$\bigcup_{N\in\mathbb{N}} V_N \subset C^2(D;\mathbb{R}^d) = C^2(D;\mathbb{R}^d).$$

Let $\{V^*_N\}_{N\in\mathbb{N}}$ be the sequence of discrete solutions defined by

$$V^*_N \in \arg\min_{V_N \in V_N \cap B^2_1-\varepsilon} \tilde{J}(V_N). \quad (4)$$

Then, under the assumptions of Theorem 1, $\{V^*_N\}_{N\in\mathbb{N}}$ is a minimizing sequence of $\tilde{J}$.

Proof. We follow closely the proof of the classic result on the convergence of Ritz methods given in [14, Sect. 40.1].

Let $\mu \in \mathbb{R}$ be the infimum of (3). Note that $\mu > -\infty$. Let $a > 0$, and let $V \in B^2_1-\varepsilon$ satisfy

$$\tilde{J}(V) < \mu + a.$$ 

By continuity of $\tilde{J}$, $V$ can be rescaled so that

$$\|V\|_{C^2(D;\mathbb{R}^d)} < 1 - \varepsilon \quad \text{and} \quad \tilde{J}(V) < \mu + 2a.$$ 

Let $b > 0$, and let $N = N(b) \in \mathbb{N}$ be sufficiently large. Then, there exists a $V_N \in V_N \cap B^2_1-\varepsilon$ that satisfies

$$\|V - V_N\|_{C^2(D;\mathbb{R}^d)} < b.$$ 

Furthermore, for $b = b(a)$ small enough, it holds

$$\tilde{J}(V_N) < \mu + 3a.$$
Let $V^*_N$ be defined as in (4). It holds
\[ \mu \leq \tilde{J}(V^*_N) \leq \tilde{J}(V_N) \leq \mu + 3a. \]
Since $a$ is arbitrary, it follows
\[ \lim_{N \to \infty} \tilde{J}(V^*_N) = \mu. \]

Remark 4. More sophisticated convergence theories can be found in [12,13,18]. The articles rely on a parametrization of the boundary, and consider as admissible shapes those that can be reached via a normal perturbation of the boundary $\partial \Omega_0$. In this case, uniqueness of the optimal solution can be achieved, and a priori convergence rates can be proved.

3 PDE constrained shape optimization

In PDE constrained shape optimization, the goal is to find the domain $\Omega$ that minimizes the functional $J(\Omega, u)$ subject to a PDE constraint $Au = f$ in $\Omega$. Here, $A : X(\Omega) \to X(\Omega)^*$ denotes a second order $X(\Omega)$-elliptic operator between the Hilbert space $X(\Omega)$ and its dual $X(\Omega)^*$, which are function spaces on the domain $\Omega$. Similarly as in (2), the shape optimization problem can be recast in a parametric form relying on the characterization of admissible domains (1), that is,
\[ \inf_{V \in B_{1-\varepsilon}} \tilde{J}(V, u), \quad \text{subject to} \quad \tilde{A}_V u = \tilde{f}_V \text{ in } \Omega_0. \] (5)

Both the elliptic operator $\tilde{A}_V : X(\Omega_0) \to X(\Omega_0)^*$ and the linear functional $\tilde{f}_V \in X(\Omega_0)^*$ depend on the vector field $V$ and are created in a way so that $u \in X(\Omega_0)$ is the solution to $\tilde{A}_V u = \tilde{f}_V$ in $\Omega_0$ if and only if $\hat{u} := u \circ T_V^{-1} \in X(\Omega)$ is the solution to $A\hat{u} = f$ in $\Omega$.

The idea of recasting both the shape functional and the PDE constraint on a reference domain is not new to shape optimization. It has already been used, for instance, in [8,13,20,21], and is, de facto, the standard approach for shape optimization based on free-form deformations; see [7,19] and references therein.

Example 1. The parametric form of the shape optimization problem
\[ \inf_{V \in \mathcal{U}_{ad}(\Omega_0)} \int_{\Omega} j(u)dx, \quad \text{subject to} \quad \Delta u = f \text{ in } H^1_0(\Omega), \] (6)
where \( j \in C^1(\mathbb{R}) \) and \( f \in H^{-1}(\Omega) \), reads

\[
\inf_{V \in B_{1-\varepsilon}} \int_{\Omega_0} j(u)(\det DT_V)dx, \quad \text{subject to} \quad \tilde{A}_V u = \tilde{f}_V \text{ in } H^1_0(\Omega_0),
\]

where the pullback \( T^*_V \) is defined as the composition \( T^*_V(f) := f \circ T_V \), and

\[
\]

Assuming continuity of the map \( V \mapsto \tilde{J}(V, u) \) on \( C^1(D; \mathbb{R}^d) \), an approximate solution of (5) can be obtained as in Theorem 2 by computing

\[
V^*_N \in \arg\min_{V_N \in V_N \cap B_{2-\varepsilon}} \tilde{J}(V_N, u), \quad \text{subject to} \quad \tilde{A}_{V_N} u = \tilde{f}_{V_N} \text{ in } \Omega_0
\]

for \( N \) large enough. The approximate optimal solution \( V^*_N \) must satisfy the variational inequality [15, Thm 1.48]

\[
d\tilde{J}(V^*_N, u; W_N - V^*_N) \geq 0 \quad \text{for all } W_N \in V_N \cap B^2_{1-\varepsilon},
\]

where \( d\tilde{J} \) denotes the Fréchet derivative of \( \tilde{J} \). It can be retrieved with descent methods, which converge in \( C^1(D; \mathbb{R}^d) \) due to the compactness of \( V_N \cap B^2_{1-\varepsilon} \). More details on the algorithm are given in Section 4.

**Remark 5.** In example 1, a minimizing sequence \( \{V^*_N\}_{N \in \mathbb{N}} \) of (8) has a subsequence \( \{V^*_N_i\}_{i \in \mathbb{N}} \) that converges strongly in the \( C^1(D; \mathbb{R}^d) \)-norm to a \( \hat{V} \in C^1(D; \mathbb{R}^d) \). Therefore, the ellipticity constants of \( \{\tilde{A}_{V_N_i}\}_{i \in \mathbb{N}} \) are bounded from below by a constant \( c > 0 \). This implies that

\[
\|u_{\hat{V}} - u_{N_i}\|_{H^1(\Omega_0)} \to 0 \quad \text{as } i \to \infty,
\]

where \( u_{N_i} \) is the solution to \( \tilde{A}_{V_{N_i}} u = \tilde{f}_{V_{N_i}} \) and \( u_{\hat{V}} \) is the solution to \( \tilde{A}_{\hat{V}} u = \tilde{f}_{\hat{V}} \), see [2, Lemma 5.3]. With this result it is easy to show \( C^1(D; \mathbb{R}^d) \)-continuity of the constraint functional (7).

## 4 Algorithm and implementation

We focus on the optimization problem (8). Let \( \Omega_0 \subset D \) be an initial guess. As trial space \( V_N \), we choose the space spanned by multivariate B-splines of degree 3 generated on a regular grid that covers the hold-all domain \( D \); see [17, Sect. 7.3]. Note that the hold-all domain \( D \) can be chosen to have a
simple shape, e.g., a product domain. More precisely, vector fields belonging to $V_n$ can be written as

$$V_N = \sum_{i=1}^{N} B_i \sum_{j=1}^{d} c_i^j e_j,$$  \hspace{1cm} c_i^j \in \mathbb{R}, \hspace{1cm} (10)$$

where $B_i$ denotes the $i$-th multivariate B-spline of degree 3, and $e_j$, $j = 1, \ldots, d$, are basis vectors of $\mathbb{R}^d$.

The trial space $V_N$ fulfills the assumptions of Theorem 2: it contains tensorized polynomials by Marsden’s Identity \cite[Sect 4.3]{17}, and it is $C^2(\overline{D}; \mathbb{R}^d)$-conforming because multivariate B-splines of degree 3 are twice continuously differentiable by construction. Moreover, B-splines have compact support and are polynomial in each grid cell. These two properties are crucial for an efficient implementation of the algorithm. Finally, using B-splines defined on a regular grid greatly simplifies the implementation, because the B-splines $B_i$ are obtained by translating a single “mother” function \cite[Sect. 7.3]{17}.

As mentioned in Section 3, an approximation of the discrete optimal solution $V_N^*$ can be retrieved with descent methods, which rely on the Fréchet derivative $d\tilde{J}$ of $J$. Formulas for the Fréchet derivative of $\tilde{J}$ can easily be derived with the Lagrangian approach described in \cite[Sect. 1.6.4]{15}. Note that this approach is simpler than the Lagrangian approach for deriving the Eulerian derivative of $J(\Omega, u)$ described in \cite{10}; indeed, in the parametric approach described in Section 3, the function space to which $u$ belongs is independent of the control parameter $\mathcal{V}$.

**Remark 6.** The Fréchet derivative of $\tilde{J}(\cdot, u)$ at $V$ evaluated in the direction $W$ is equal to the Eulerian derivative of $J(T_V(\Omega), u)$ in the direction $W \circ (T_V^{-1})$, because $T_{V+W} = T_{W \circ T_V^{-1}} \circ T_V$.

**Example 2.** The Fréchet derivative of $\tilde{J}$ from (7) reads

$$d\tilde{J}(V; u; W) = \int_{\Omega_0} \left( j(u) - fp \right) \partial_W (\det DT_V)$$

$$- \grad f \cdot Wp \det DT_V + \grad p \cdot \partial_W M_V \grad u \, dx,$$

where

$$\partial_W M_V := \det(DT_V) \left( \tr(DT_V^{-1}DW) DT_V^{-1}DT_V^{-T} - DT_V^{-1}(DT_V^{-T}DW + DWDT_V^{-1})DT_V^{-T} \right),$$

$$\partial_W (\det DT_V) := \det(DT_V) \tr(DT_V^{-1}DW),$$

and where $p \in H^1_0(\Omega_0)$ is the solution to an adjoint problem

$$- \text{div}(M_V \grad p) = -j'(u)(\det DT_V) \text{ in } H^1_0(\Omega_0).$$
As Example 2 clearly illustrates, the Fréchet derivative of PDE constrained functionals depends on the solution \( u \) of the state problem and, possibly, on the solution \( p \) of the adjoint problem. As explicit analytic solution of these boundary value problems are usually not available, one can replace them with approximate solutions, at the cost of introducing a perturbation error when solving the first order optimality condition (9). In particular, this perturbation error both affects the quality of the descent solutions and the stopping criteria in Algorithm 1 on page 10.

We consider here approximations by means of the finite element method. When stated as a volume integral, the map \( u \mapsto d\tilde{J}(V; u; W) \) is usually continuous with respect to the energy norm of \( u \). Therefore, relying on standard duality techniques, one can expect to observe superconvergence in the approximation of the operator \( \tilde{J}(V; u; \cdot) \) when the solution \( u \) is replaced by its finite element counterpart \( u_h \). The same holds for evaluating the shape functional \( \tilde{J}(V, u) \). In particular, we consider linear Lagrangian finite elements on quasi-uniform triangular meshes. In this case, it can be shown that

\[
|d\tilde{J}(V; u; W) - d\tilde{J}(V; u_h; W)| = C(V)h^2\|W\|_{W^{2,4}(\mathbb{R}^d, \mathbb{R}^d)}^2, \tag{11}
\]

where \( h \) denotes the width of the finite element mesh. On the other hand, we do not observe superconvergence in (11) when \( d\tilde{J} \) is recast as an integration on the boundary \( \partial \Omega_0 \). We refer to [16] for more details.

The approximate optimal solution \( V_N^* \) is computed iteratively with a projected gradient method as illustrated in Algorithm 1 on page 10. The next paragraphs give a detailed description of the algorithm’s steps.

In Line 7 we compute the descent directions. Since the Fréchet derivative \( d\tilde{J}(V; u; \cdot) \) belongs to the dual space of \( C^2(\overline{D}; \mathbb{R}^d) \), its descent direction is usually defined as the solution of [15, Page 103]

\[
\inf_{\|W\|_{C^2(\overline{D}; \mathbb{R}^d)} = 1} d\tilde{J}(V; u; W).
\]

However, such a descent direction may not exist because the space \( C^2(\overline{D}; \mathbb{R}^d) \) is not reflexive. Employing knowledge on the shape Hessian is also not straightforward, because the second order Fréchet derivative \( d^2\tilde{J} \) cannot be expected to be coercive. Indeed, for any vector field \( W \) tangential to \( \Omega_0 \) as well as for vectorfields with a compact support that does not intersect \( \partial \Omega_0 \), it holds\(^1\)

\[
d\tilde{J}(V; u; W) = 0 \quad \text{and} \quad d^2\tilde{J}(V, u; W, W) = 0.
\]

\(^1\)The shape gradient \( d\tilde{J}(V; u; W) \) is well-defined for any vector field \( W \in W^{1,\infty}(\mathbb{R}^d, \mathbb{R}^d) \), whilst the shape Hessian requires at least \( W \in W^{2,\infty}(\mathbb{R}^d, \mathbb{R}^d) \) [10].
Therefore, we consider here descent directions given as $H^1$-representatives of the Fréchet derivative, that is, solutions to the linear system of equations

$$
\min_{\|W\|_{H^1_{\Omega_{0}}} = 1} d\tilde{J}(\mathcal{V}, u; W).
$$

We point out that this choice is arbitrary. Other metrics as well as the use of $d^2\tilde{J}$ to compute optimal optimization steps are currently under investigation.

In Line 10 we project the new vector field $\mathcal{V}_{\text{temp}}^p$ on $B_1^{1-\varepsilon}$ according to the projected gradient method [15, Alg. 2.3]. This condition is quite restrictive and in the experiments it is weakened with a projection on $B_1^{1-\varepsilon}$, which still guarantees that the algorithm is well-defined. An alternative suggested in [7] is to track the value of $\det DT_{\mathcal{V}}$ and to check that it is positive and bigger than a threshold value.

**Remark 7.** It might nevertheless happen that the (continuous) optimal solution $\mathcal{V}^*$ lies on the boundary of $B_1^{1-\varepsilon}$, and that, however, the value of $\tilde{J}(\mathcal{V}^*)$ is not yet satisfactory for convergence purposes. For instance, this might be the case when the initial guess $\Omega_0$ is poorly chosen. In this situation a remedy is to select the retrieved shape as initial guess, and to start the algorithm again. Practically, this can be done either creating a new mesh of $TV^*(\Omega_0)$ or replacing the transformation $TV$ with the composition $TV \circ TV^*$ (exploiting the fact that the composition of diffeomorphisms is again a diffeomorphism). This latter approach can be made computationally affordable by simply re-evaluating all $B_i$’s on the mapped quadrature nodes; see the next paragraph on the computational complexity of Algorithm 1. Note also that Theorems 1 and 2 still hold as long as a finite number of compositions is considered.

Finally, in line 14 we guarantee the admissibility of the optimization step $\delta$ according to the Armijo rule [15, Sect. 2.2.1.1].

In each iteration, the computational cost of the algorithm is mainly due to computing the finite element solution $u_h$ in Line 6. Particularly costly are the assembly of the stiffness matrix and solving the linear system. The computational complexity of the latter depends only on the dimension of the finite elements trial space and can be reduced relying on iterative solvers or multigrid strategies; cf. [6]. On the other hand, the assembly of the stiffness matrix comprises numerical integration in each triangle and, thus, requires several calls of the costly matrix function $M_{\mathcal{V}}$, whose entries are given as a sum of basis functions, and that has to be evaluated in each quadrature point. A first reduction of this computational cost can be achieved by realizing that, by the Hadamard-Zolésio structure theorem [10, Thm 2.4], only the B-splines whose supports intersect $\partial \Omega_0$ have to be taken into account. Nevertheless,
Algorithm 1 Projected gradient method with Armijo rule

1: Select initial design $\Omega_0$, optimization step $\delta$, and parameters $\varepsilon, \gamma \in (0, 1)$
2: Initialize $V_N = 0$
3: Precompute all $B_i$'s on quadrature nodes
4: Compute $\tilde{J}^{\text{old}} = \tilde{J}(V_N)$
5: repeat
6: Compute finite element solution $u_h$ of $\tilde{A}V = \tilde{f}$ in $\Omega_0$
7: Compute $V_{new} = \text{argmin}_{W_N \in V_N, \|W_N\|_{H^1(D)} = 1} d\tilde{J}(V, u_h; W_N)$
8: Set $V_{temp} = V_N + \delta V_{new}$
9: if $\|V_{temp}\|_{C^2(\overline{D}; \mathbb{R}^d)} > 1 - \varepsilon$ then
10: \hspace{1em} Scale $V_{temp} = V_{temp} \cdot (1 - \varepsilon)/\|V_{temp}\|_{C^2(\overline{D}; \mathbb{R}^d)}$
11: end if
12: Compute $\tilde{J}^{\text{new}} = \tilde{J}(V_{temp})$
13: if $\tilde{J}^{\text{new}} - \tilde{J}^{\text{old}} > \gamma \delta \|\tilde{J}(V_N, u_h; V_{new})\|$ then
14: \hspace{1em} Update $\delta = \delta/2$ and go to line 8
15: else
16: \hspace{1em} Update $V_N = V_{temp}^{\text{temp}}$, $\tilde{J}^{\text{old}} = \tilde{J}^{\text{new}}$
17: end if
18: until $\tilde{J}^{\text{new}}$ small enough or $|\tilde{J}^{\text{new}} - \tilde{J}^{\text{old}}|$ too small

we experienced that this is not enough to obtain reasonable computational times. Therefore, before starting the optimization routine, in Line 3 we pre-evaluate all B-splines in every quadrature point once and store the values. Then, in each iteration, these values can be used to drastically reduce the computational cost of the matrix assembly, because the values of $M_V$ can be computed as linear combinations of the stored data. Additionally, these data can also be used to speed up both the computation of the descent direction in Line 7, which requires the evaluation of $d\tilde{J}(V, u_h; B_i e_j)$ for $i = 1, \ldots, N$, $j = 1, \ldots, d$, and the evaluation of the misfit functional $\tilde{J}$ in Lines 4 and 12. Note also that the memory requirement of this strategy can be reduced by exploiting the compact support property of B-splines: in each cell, just the B-splines whose support intersects that cell have to be evaluated on the quadrature points.

5 Numerical experiments

Let $\Omega_0$ be an annular domain with internal boundary $\partial \Omega_{\text{in}}$ and external boundary $\partial \Omega_{\text{out}}$. The set of admissible domains is redefined to comprise
domains obtained by perturbing only the external boundary \( \partial \Omega^\text{out} \), i.e.,

\[ U_{\text{ad}}(\Omega_0) := \{ T_\nu(\Omega_0) ; \quad T_\nu = I + \nu, \quad \| \nu \|_{C^1(\Omega_0; \mathbb{R}^d)} \leq 1 - \varepsilon, \quad \text{supp } \nu \cap \partial \Omega^\text{in} = \emptyset \} . \] (12)

We consider the shape optimization problem

\[ \inf_{\Omega \in U_{\text{ad}}(\Omega_0)} \int_{\Omega} (\nabla u)^2 + g^2 \, dx \quad \text{subject to} \quad \begin{cases} -\Delta u = 0 & \text{in } \Omega, \\ u = 0 & \text{on } \partial \Omega^\text{out}, \\ u = 1 & \text{on } \partial \Omega^\text{in}, \end{cases} \] (13)

where \( g \) is a constant.

Such an optimization problem stems from the class of Bernoulli exterior free boundary problems, which are used as a benchmark in shape optimization because they admit stable minimizers [11].

The parametric form of (13) reads

\[ \inf_{\Omega \in U_{\text{ad}}(\Omega_0)} \int_{\Omega_0} \nabla u \cdot M_\nu \nabla u + g^2 | \det D T_\nu | \, dx \] (14)

subject to

\[ \begin{cases} -\text{div } M_\nu \text{grad } u = 0 & \text{in } \Omega_0, \\ u = 0 & \text{on } \partial \Omega^\text{out}_0, \\ u = 1 & \text{on } \partial \Omega^\text{in}_0, \end{cases} \]

where \( M_\nu := (\det D T_\nu)^{-1} D T_\nu^{-T} \). The Fréchet derivative of the shape functional in (14) reads

\[ d\tilde{J}(\nu; \omega) = \int_{\Omega_0} \nabla u \cdot (\partial_\nu M_\nu) \nabla u + g^2 (\partial_\nu \det D T_\nu) \, dx . \] (15)

Note that, in contrast to Example 2, formula (15) does not involve the solution of an adjoint problem [12].

Henceforth, we set \( g = (1.2 \ln(2.4))^{-1} \), so that the external boundary of the optimal solution is a circle of radius 1.2 centered in the origin. In all the experiments, we consider finite element solutions computed with linear Lagrangian finite elements on quasi-uniform triangular meshes. Integrals in the domain are computed by a 3-point quadrature rule of order 3 in each triangle. The boundary of the computational domain is approximated by a polygon, which is believed not to affect the convergence of linear finite elements [9, Sect. 10.2]. The optimization step \( \delta \) is initially set to \( \delta = 0.3 \) and the parameter \( \varepsilon \) to \( \varepsilon = 0.1 \). Finally, instead of the Armijo rule condition, we just check that the absolute error does not increase in line 14 of Algorithm 1 on page 10.

To show that the algorithm proposed in Section 4 is feasible, we select \( \partial \Omega^\text{out}_0 \) to be an ellipse with major semi-axis of length 1.5 and minor semi-axis of length 1.3, whilst \( \partial \Omega^\text{in}_0 \) is a circle of radius 0.5 centered in the origin.
The domain $\Omega_0$ is covered with a regular grid of width 0.255 over which the trial space $V_N$ is constructed. The finite element solution $u_h$ is computed on the mesh displayed in Figure 1 (first row, left). Despite the coarseness of the mesh and the low resolution of the B-spline grid, after twelve optimization steps we already recover a satisfactory approximation of the target boundary; see Figure 1 (first row, right).

The experiment is repeated for a different initial design (an ellipse with major semi-axis of length 1.5 and minor semi-axis of length 1.1). Again, after twelve steps we recover a satisfactory approximation of the target boundary; see Figure 1 (second row).

Next, we investigate the impact of the finite element approximation on the retrieved approximate optimal solution. We keep the trial space of B-splines $V_N$ fixed (with width 0.255), and we generate 5 additional meshes through uniform refinement of the one displayed in Figure 1 (during the refinement the boundary nodes are projected onto $\partial \Omega_0$). Let

$$\text{err}^{(i)} := \frac{|\tilde{J}(V_N^{(i)}, u_h) - \tilde{J}_{\text{min}}|}{\tilde{J}(I, u_h)}$$

be the scaled absolute error obtained after $i$ steps of Algorithm 1. In Figure 2 (left) we plot the the evolution of $\text{err}^{(i)}$ for each mesh. We see that after 20 iterations the errors saturate. In Figure 2 (right) we plot $\text{err}^{(30)}$ for each mesh versus its mesh width. We observe an algebraic convergence with rate 1.7.

We remark that $\tilde{J}(V, u_h)$ itself converges quadratically in the mesh width $h$ (uniformly in $V \in C^2(D; \mathbb{R}^d)$).

Finally, we investigate the impact of the resolution provided by $V_N$ on the approximate optimal solution. We perform the experiment on the fourth mesh of the previous experiment. In Figure 3 we show the evolution of $\text{err}^{(i)}$ for $V_N$ constructed on a regular grid of width 0.51 (blue line) and 0.255 (black line). The former trial space comprises 54 active basis function, whilst the latter has 152 active basis functions. We see that the resolution of $V_N$ affects the quality of the retrieved approximate optimal solution. However, it is not simple to guess the optimal resolution of $V_N$. A fine regular grid produces basis functions with small support, and thus, with higher $C^1(D; \mathbb{R}^d)$-norm (for fixed $C^0(D; \mathbb{R}^d)$-norm). There is, hence, a trade-off between the resolution of the spline space and the maximal displacement that it can reproduce. Additionally, it has to be taken into account that the smaller is the support of the basis functions the lower is the accuracy in evaluating the shape gradient. Therefore, we suggest to pursue an adaptive strategy by starting with a relatively coarse resolution and, when the iteration stagnates, to embed the so far computed discrete vector field on a nested space spanned by basis
Figure 1: Numerical experiment 1 (first row) and 2 (second row). Left: The initial guess $\Omega_0$ is covered with a regular grid used to generate cubic B-splines. Orange dots indicate the lower left corner of the support of the active B-splines. The orange square in the top right corner indicates the support of a cubic B-spline. A triangular grid (purple) is generated on $\Omega_0$ to compute the finite element solution $u_h$. Right: approximate optimal boundary retrieved after twelve iterations of Algorithm 1. Despite the coarseness of the mesh and the low resolution of the B-spline grid, we recover a decent approximation (blue line) of the target boundary (cyan line). Red lines indicate the boundary of the initial guess $\Omega_0$. 
functions generated on a grid with half width [17, Sect. 7.6]. Then, new
descent directions are computed by taking into account only the new basis
functions that intersect the boundary, whilst the ones that do not intersect
the boundary are kept to provide a smoother decay of the vector field. The
evolution of $\text{err}^{(i)}$ for this strategy is displayed in Figure 3 (red line). We see
that we are able to improve the quality of the approximate optimal solution
by switching to a finer space after 10 iterations.

6 Conclusions

We presented a method to compute approximate optimal solutions of elliptic
PDE constrained shape optimization problems. Shapes are identified with
diffeomorphisms and the shape optimization problem is recast as an opti-
mal control problem. The latter is then stated on a finite dimensional trial
space based on cubic B-splines pursuing a Ritz approach. Under reasonable
assumptions, the solution of the finite dimensional problem converges to the
solution of the original problem.

To solve the finite dimensional problem we rely on descent methods.
Superconvergence in the approximation of the Fréchet derivative can be
achieved relying on FE discretizations of the underlying BVP. Numerical
experiments show that accuracy in the approximation of the Fréchet deriva-
tive directly affect the quality of the retrieved approximate optimal solution.
Figure 3: Evolution of the scaled absolute error (16) for a coarse (blue line) and a finer (green line) trial space $V_N$. Switching to a finer space after 10 iterations, it is possible to start with a coarse trial space and still retrieve an approximate solution with good quality (red line).

Finally, we discussed an adaptive strategy based on nested trial spaces to balance discretization errors due to B-splines approximation of shapes and FE approximations of the solution of the PDE constraint.
